Introduction

Abnormal Placentation carries life-threatening consequences to the mother. Several types of abnormal placentation exist (Accreta, Increta, and Percreta). The different types vary depending on the degree of myometrial involvement. The accreta type is most common and easier to manage. The increta and percreta varieties are less common, difficult to manage and associated with severe maternal morbidity and mortality as a result of postpartum hemorrhage [1].

Placenta percreta is a rare complication of pregnancy. It occurs mostly in the third trimester and presents with severe postpartum hemorrhage and placenta retention. It is rare in the second trimester of pregnancy. Placenta percreta is becoming more common as cesarean section and other uterine surgeries increase. The presence of a uterine scar remains a major risk factor [2]. We here present a rare presentation of placenta percreta occurring in the second trimester as an acute abdomen secondary to uterine rupture and intra-abdominal hemorrhage. She had a life-saving total hysterectomy and good postoperative recovery period. This might be the first case to be presented from Middle east with such scenario. Careful evaluation of a pregnant lady with an acute abdomen must be done with consideration of abnormal placentation as a cause, especially in a patient with risk factors for abnormal placentation.

Case Description

A 45 years old G4P3+0 Saudi lady at 22 weeks gestation presented to Security Forces Hospital Emergency Department with acute onset of Abdominal Pain that started few hours prior to presentation. Patient has sought medical advice in a private hospital and diagnosed as an acute appendicitis. The patient has left...
the private hospital and presented to Security Forces Hospital for another opinion. The pain had progressively increased in intensity and was associated with nausea and vomiting. Her past medical history included hypothyroidism on Levothyroxine. Previous surgical history included 3 low transvers cesarean deliveries.

On presentation, the patient’s blood pressure was 90/52, her heart rate was 120bpm, oxygen saturation was 98% in room air; examination revealed diffuse abdominal tenderness. Pelvic Bedside scan revealed a single viable intrauterine pregnancy going with 22 weeks. Abdominal Ultrasound was not conclusive, so a decision was made for diagnostic laparoscopy to rule out appendicitis.

The laparoscopy scope revealed an abdomen full of blood. The surgeons converted to laparotomy. A Midline supra-umbilical incision was made but they did not find the source of bleeding. Vascular surgeon has joined the surgical team as the primary surgeons has suspected a rupture aneurysm. They extended the abdominal incision below the umbilicus and surgeons saw the source of bleeding. It was a uterine rupture just above the bladder and bleeding coming from the placenta. Obstetricians and Gynecologists were called and joined the procedure and a decision for hysterectomy was made. It was a challenging hysterectomy as the pelvis was full of blood, the placenta has invaded of the lower segment and part of the bladder, left broad ligament and the upper vagina, and the tissue are very fragile to be held by clamps. Vascular surgeons while doing bilateral internal iliac artery ligation, the right ureter was injured. After the hysterectomy was complete, a piece of the placenta was left attached to the upper vagina, with no bleeding (Figure 1). Urologist did ureter reimplantation and bladder repair. Abdomen was irrigated with 6 liters normal saline and hemostatic agents were placed, hemostasis was achieved. Patient was shifted to intensive care unit. She received a total of 12 Packed Red Blood Cells, 12 Units of Platelets, and 12 Units of Fresh Frozen Plasma. Her Hemoglobin dropped intra op to 4 g/dl. Her post-operative, post transfusion hemoglobin was 9 g/dl. She had an uneventful postoperative recovery period.

**Discussion**

Placenta percreta is characterized by the invasion of the chorionic villi through the myometrial and serosal layer of the uterus, typically in the absence of normal decidualized endometrialstroma. This absence of the decidua basalis leads to a clinically adherent placenta. Uterine instrumentation, previous cesarean section, and other procedures causing myometrial scarring all increase the risk of abnormal placenta 

The incidence of abnormal placenta is relatively low, and demographic data about it is limited to small series and case reports [1]. The average incidence is estimated at 1 in 7000 deliveries [2]. Placenta percreta represents 5 to 7% of all abnormal placenta [3,4]. Even though rare and difficult to diagnose, it remains very important because of its possible fatal outcome with a reported maternal mortality rate of 2 to 7% [5,6]. The diagnosis is even more difficult when this occurs in the second trimester as was the case in our patient. However, the presence of a previous classical scar and her age were risk factors for the disease.

Though the cause of placenta percreta as reported by Morken et al. [7] is unknown, several risk factors have been associated with this condition notably, placenta praevia, a previous caesarean section, multiple pregnancies, a history of dilatation and curettage, high parity and increasing maternal age. The patient therefore had some risk factors as noted above and the placenta was found adherent to the previous scar, a finding that was not known to us as the patient was unbooked in our hospital. A previous scar is a major risk factor as the decidua basalis in this zone is expected to be poorly vascularized and presents as a zone of weakness for subsequent placental villi penetration [1].

Clinical presentation is variable with Antepartum hemorrhage is a usual scenario [8]. However, it is usually seen in the third trimester. The presentation here is rare since it occurred in the second trimester rendering clinical suspicion difficult as was evident in the case. Other reports indicate that placenta percreta can present as an acute abdomen [7] or even painless hematuria following bladder invasion [9].

Several diagnostic modalities may facilitate the antepartum diagnosis of abnormal placenta. These include transvaginal and trans-abdominal ultrasound with color imaging, and magnetic resonance imaging (MRI). Finberg et al [10] reported a sensitivity of 94% and a specificity of 79% for prenatal ultrasound in diagnosing the morbid placenta adhesion. One Bedside ultrasound was done for our patient, nevertheless the diagnosis was missed. This was probably due to the inexperience of the ultra sonographer, a factor which greatly prejudices the antepartum diagnosis.

The management of placenta percreta follows one of two options, radical surgery (hysterectomy) or conservative management [11]. Traditionally, abdominal hysterectomy is the treatment of choice for placenta percreta and indicated in cases of severe hemorrhage [7].

Though the conservative approach is believed to carry a higher risk of maternal death it preserves fertility and provides some psychological support to the woman [6]. It involves either of the
following procedures: leaving the placenta in place with packing; a piecemeal blunt dissection with packing; uterine curettage with packing; closing of the uterine defect; localized excision and uterine repair; uterine packing with uterine or even hypogastric artery ligation; bilateral uterine artery embolization; and pelvic artery ligation [6,12,13]. Our patient had the radical approach due to the severe bleeding that she had, and it was a life-saving surgery.

The major complication of placenta percreta is severe bleeding. This can be associated with hypovolemic shock and subsequent death. Post-operative infection as was the case in our patient remains pertinent and life threatening. O’Brien et al. [6] reported a 28% post-operative infection rate. Other complications include uterine rupture, coagulation problems, invasion of adjacent organs, uterine inversion following manual placental removal, formation of fistulae, and of course the loss of reproductive functions.

The follow up of patients managed for placenta percreta involves strict surveillance and prompt management of complications. If it is suspected that part of the placenta is left in place, the patient would require follow up to ensure placental tissue resolution. This would involve regular clinical and ultrasound assessment and βhCG assay.

Conclusion

Placenta percreta, though a rare entity, remains a very serious clinical problem due to its life and fertility threatening consequences. Its antepartum diagnosis can be suspected based on risk factors and the clinical presentation of the patient. Its management remains difficult, but total abdominal hysterectomy with loss of fertility remains the treatment of choice especially in our case. However, conservative management may be used for minor forms of the disease (placenta acreta and increta). Such a decision must take into consideration the age of the woman, the extent of damage to the uterus, the gestational age and associated medical conditions such as diabetes, immuno-depression, cardiac and renal disorders.

Ethical Approval

Given the nature of the article, the management of the patient was not modified by the study, so it was considered exempted from IRB approval.

Patient had an informed consent for the management and permission for using the data for research study if needed.

Conflict of Interests

Author said no Conflict of Interest.
